

FLUORESCENT PROTEIN TAGS

INTRODUCTION

In this document is summary information about fluorescent tags that can be added to heterogeneously expressed proteins.

The green fluorescent protein (GFP) was first purified from *Aequorea victoria* in the 1960s and 70s (1), but it was not until the nucleotide sequence was reported in the 1990s that the full potential of GFP as a tool was realised (2, 3). Structures of GFP revealed the basis of the fluorescent chromophore as being formed by the maturation of a triplet of residues serine 65, tyrosine 66 and glycine 67 into an imidazolinone ring system (4). When heterologously expressed, GFP folds and the chromophore forms correctly in the absence of co-factors or chaperones, meaning that the sequence can be fused to other proteins to fluorescently tag them. This ability is useful in numerous experimental techniques including but not limited to fluorescent resonance energy transfer (FRET), super resolution microscopy localisation studies, flow cytometry etc. In addition, fluorescent tags can be extremely useful in the process of protein expression and purification optimisation, especially for challenging targets such as membrane proteins.

The wild-type GFP sequence has been modified with point mutations in order to modify specific properties. For example, the fluorescence intensity has been increased, the protein has been given the ability for folding in an extracellular environment, or a wide array of changes to the excitation and emission spectra have been achieved in order to create fluorescent proteins in the blue, cyan and yellow spectrum. Furthermore, fluorescent proteins from other marine species, for example *Discosoma striata* that has a red colour, have also been added and modified in a similar fashion to provide coverage of the whole colour spectrum.

COMMONLY USED FLUORESCENT PROTEIN TAGS

Wild-type GFP (wtGFP)	
Excitation (nm)	395
Emission (nm)	509
